MORKING SPECIFICATION MATTEL ADVANCED BRAPHIC INTERFACE CIRCUIT

O.O PREVIEW

The MAGIC chip will be the core of Mattel's second generation TV game. As one of two custom ICs planned for this design, it will be responsible for generating composite video, controling the dynamic RAM memory, providing system clocking and integrating miscellaneous SSI and MSI functions for minimum chip count. Since the CPU selection has not been made at this time, this paper assumes the author's favorite, the Motorola 68000.

1.0 POWER

MAGIC will operate with only a +5 volt supply. It is expected that a number of power and ground pins and carefull chip layout will be necessary to allow proper decoupling of the video D/A converter.

2.0 RAM INTERFACE

The MAGIC chip will require direct access to a minimum of 16K words (16 bit) of RAM. Since the base system is projected to have 16K words of RAM, the CPU must also access this same RAM. To provide maximum CPU speed, the RAM data and address buses will be isolated from the CPU buses except during CPU accesses. To insure maximum CPU speed the MAGIC chip will interleave it's accesses with those of the CPU and internally pipeline data to allow immediate CPU access. In addition, the MAGIC chip will provide all RAM control signals (RAS, CAS, Enable, and address multiplex) and refresh management. The control and refresh design will accommodate 16K x 4 dynamic RAMs; the selected type should be dual sourced and is subject to Mattel Electronics approval. If possible, the design should also handle 64K x 4 (256k) RAMs.

3.0 CPU INTERFACE

MAGIC will provide the clock for the CPU. This clock will be at twice the color subcarrier frequency; 7.16 MHz for NTSC and 8.86 MHz for PAL and SECAM. These frequencies are the system crystal frequency divided by 2.

MAGIC will provide two different types of interupt signal to the CPU over a single line (-IPL2). The first of these will occur at the horizontal line rate divided by 256. Since both 525 and 625 line systems use nearly the same line rate

this will result in an interupt that occurs at nearly 60 Hz regardless of TV system. This interupt will be used for system timing functions to make games that play at the same speed on both 525 and 625 line systems. The second type of interupt will occur when the active scanning line on the TV screen passes a line number stored by the CPU in a MAGIC register. This interupt is intended primarily to allow the moving objects to be reused (details in the moving object Unless the second type of interupt is disabled, section). it will be necessary for the CPU to read a register to determine which has occured. Note that the timing interupt is asynchronous with both 525 and 625 line vertical field rates; this means that often the timing interupt will occur during the active picture and occasionaly both interupts will occur at the same time.

How ?

Communication between the CPU and MAGIC is through 6 control lines, 16 data lines and 13 of the 19 system address lines. The control lines are -AS, R/-W, -DTACK, -UDS, -LDS and -RESET. The functions of these lines are fully described in the 68000 literature. RAM data in and out of MAGIC and data communication between the CPU and MAGIC through the external bidirectional buffer use the same 16 data lines. addition, data communication between the RAM and the CPU use the same bidirectional buffers. An output from MAGIC enables the buffers, while the R/-W line controls the Obviously, the RAM interface mentioned above direction. must work closely with the graphics generators and the CPU interface to prevent conflict in the use of data lines and The 13 address lines are split into two groups; 8 low order (A1 through A8) and 5 high order (A15 through A19). the remaining 6 mid order lines (A9 through A14) are not available to MAGIC; they are, however, routed to the RAM through an external buffer (further description in the RAM interface section). The 8 low order lines allow selection within MAGIC of 256 control registers and are also passed through to the RAM during CPU accesses, reducing external multiplexing. The 5 high order lines allow decoding to 16K word blocks to enable the MAGIC and RAM as shown in the system address map. Outputs from this decoder also go external to the sound chip (1-16K space), cartridge (1-32K space), Exec ROMs (2-32K spaces) and language ROMs (2-32K These outputs would be the first to go in a pin-out crunch, since they are only saving a simple TTL decoder.

4.0 TV SYNC TIMING AND CONTROL

All system timing is derived from a 14.32 MHz fundamental mode crystal (17.72 MHz for 625 line systems). This crystal will be trimmed to 4 times the chroma subcarrier frequency

in NTSC and PAL systems. To allow locking the system to an external video source, a connection will be available to allow slight changes to the crystal frequency under phase lock control. The oscillator divided by 2 forms the CPU clock and divide by 2 and divide by 4 signals go to the video output section to generate the chroma subcarrier.

Dividing the oscillator by 2.5 produces the pixel clock. A discussion of pixel size is in the graphics generator section, but I mention here that we are generating a full interlace TV signal complete with equalizing pulses and serrated vertical sync pulse. This is being done for two primary reasons. First, it will enable mixing external video with MAGIC generated video and second, it is expected that non-standard signals will suffer varying degrees of performance degradation as TVs use more and more digital signal processing. It is even possible that complete incompatability could result. In addition to full interlace the picture will be 24 rows of 40 alpha-graphic cards. Each card will be 6 pixels wide and 8 pixels high (one pixel is two interlaced lines high). A non-interlaced mode will be available under software control to improve the appearance of alpha characters.

The horizontal line is 364 pixels long; of these the active picture is 240 pixels, blanking and sync require 75 pixels, the left border is 28 pixels and the right border is 21 pixels. In 625 line systems the left border has 73 and the right border has 66 pixels. Note that the left border is 7 pixels wider that the right; this allows for the tendancy of TVs to cut off more of the left side of the picture and results in a better centered picture. To allow simplicity economy in the picture generation circuits, the horizontal counter must have the same counter outputs for the active portion of the line for both 525 and 625 line It is also desirable that the counter output during the blanking, sync, etc. are the same in both This can be achieved by resetting the counter to zero 16 pixels before the end of the left border. At the count of 256, the active picture ends and the right border starts. For 625 line systems, the start of the blanking is at 322 and the end of blanking is at 397. At 454 the counter is reset to zero completing the 454 pixel line. For 525 line systems, the counter is forced to skip from 277 to 322; shortening the border by the required 45 pixels and allowing the decoders to generate blanking, sync, etc. When the count reaches 409 it is reset to zero completing the 364 pixel line (45 counts were skipped at end of right border, 409-45=364). Starting the count 16 pixels under the border allows 16x16 pixel moving objects to completely "hide" under the left border and leave only one pixel exposed on the right border; using only an 8 bit X location. When the background is in the scroll mode, the left border will cover an additional 6 pixels (one card width).

The output of the horizontal counter is divided by 2 as a line alternation signal to the video output section to generate PAL and SECAM. This output is further divided by 128 to generate the timer interupt at 61.4 Hz (60.99Hz in 625 line systems).

The vertical counter counts 525 or 625 depending the system being generated. As in the horizontal counter, it is convient to arrange the start of the counter and skip counts to simplify the decoding. In this case, the counter is forced to skip once during the frame for 625 line systems and three times for 525 line systems; fortunately, two of the three 525 line system skips are exactly alike from decode and preset standpoints.

First, the 625 line system. Vertical blanking is 21 lines in each field. The top border is 51 lines in field 1 and 50 lines in field 2, the bottom border in each field is 49 lines and the active picture is 192 lines in each field. The lower 9 bits of the 10 bit vertical counter must be the during the active picture lines since the same information is presented during each field (each pixel is 2 interlaced lines high). Again the counter is reset to zero 16 lines before the end of the top border allowing the moving objects to "hide" under the border. At line count 208, the bottom border starts, at count 257, the blanking for field 2 starts, at count 278, the top border for field 2 starts. At count 312 the counter is skipped to 512; resetting the low 9 bits to zero, as desired to scan the active lines for field 2. Count 720 brings the end of the active lines and start of the border. Count 769 ends the bottom border of field 2 and starts the blanking and sync for field 1. Field 1 blanking ends and the top border starts at 790. At 825 the counter is reset to zero completing the frame (200 counts were skipped, 825-200=625).

For 525 line systems the skip at 312 becomes a skip from 287 to 512 and the reset to zero happens at 800, causing 25 additional border lines to be skipped each place. 25 border lines are also skipped in each field at the end of the bottom border by skipping from 232 to 257 and 744 to 769.

When the background is in the scroll mode, 8 additional lines (1 card height) become border at the top of the active picture in each field. Non-interlace mode is achieved by forcing bit 10 to remain high, causing field 2 picture and field 1 blanking and sync to repeat (313 lines/625 system,

263 lines/525 system). MABIC will syncronize to an external source by providing composite sync to an input pin.

Decoders are provided to generate composite sync, composite blanking, burst gating, SECAM "bottle" and PAL "meander gate" burst blanking signals from the combined outputs of the horizontal, vertical and line alternation counters.

VIDEO OUTPUT

The video output section receives signals from the graphic and alpha generators, a pixel clock, Fsc and 2 Fsc, line alternation (for PAL and SECAM) and PAL/NTSC/SECAM control. Its output, from a primary and a secondary D/A converter, are composite video for NTSC/PAL and Y and composite color difference for SECAM. There is also an output for use with an external video mixing gate.

Two video outputs allow spliting the graphic and alpha generator outputs to two televisions. An application for this split output is two player games where the players each have their own display with both common and private information. Another application would be dual user systems where one group uses the graphics for a game while someone else uses the alpha for kitchen, den or study applications. An optional dual output modulator will be necessary to implement this function. Alternately, the optional unit may contain only the second modulator, with the original modulator plugging into it to provide dual outputs. Since SECAM uses both DACs to produce a single video output, the split graphics/alpha mode is not available.

A 16 bit register controls the spliting function. The following assignments are made:

5 bit Graphic split 5 bit Alpha split

1 bit H or V split

1 bit Graphic overlap on/off

1 bit Alpha overlap on/off

1 bit Braphic split on/off

1 bit Alpha split on/off

1 bit Alpha flip on/off

The 5 bits allow selection of any of the 24 rows or column 4 through 35, depending on the sense of the H/V bit. With the graphic overlap off, the primary output displays the graphic generator output from the top down to the selected row or from the left across to the selected column. The secondary output displays the remaining graphic output. When the graphic overlap bit is on, the primary output displays to the lower (or rightmost) split and the secondary output

displays from the upper (or leftmost) split. Normally the primary output displays alpha to the alpha split and the secondary output displays from there. With alpha overlap on, the primary displays to the lower (or rightmost) split and the secondary displays from the upper (or leftmost) split. The use of upper/lower for overlap allows a display that has a graphic overlap, but the alpha in the overlap area is switched between the primary and secondary outputs. This alpha could be an overlay of a map graphic showing private information alternatly to each player. The graphic and alpha split on/off enables the spliting functions; when off, full graphics and/or alpha are on both outputs. A one in the alpha flip bit causes the split alpha to swap outputs (primary to secondary and secondary to primary). This allows displays with the top half graphics and bottom half alpha from the primary output and the reverse from the secondary output.

The primary and secondary DACs will be four binary ratioed MOS transistors connected to sink current. Inputs to the DACs will also include sync, blanking, burst gate and NTSC/PAL control. The external gating output is asserted when the display color code is zero. A suitable delay is inserted in this signal to match it to the processing delay that the video generation will require.

Background and display color outputs from the graphic generators select outputs from the color map registers. There are 16 color map registers, each 12 bits wide. Four bits of each register describe the Y (luma) level. Four bits each describe the two color difference (R-Y and B-Y) levels. These are encoded as a sign bit with 3 maginitude bits. First the Y levels. For the background color, only the Y value is selected and is combined with the display Y value when the pixel is a moving object edge. One bit of the Y adjust signal indicates an edge; the remaining bits are data used to adjust the Y value. The adjustment method varies depending on the mode of the graphic generator; for more information see the graphic generator section.

The selected color difference signals are passed through the 4 pixel averagers to limit the bandwidth. The averaged color difference signals are then assembled with the Y signal to generate the required composite signal. This assembly is performed by dividing the color cycle into four quadrants. In the first quadrant, the R-Y is added to the Y; in the second quadrant, B-Y is added to Y; in the third quadrant R-Y is subtracted from Y; in the fourth quadrant, B-Y is subtracted from Y. The MUX and adder/subtractor that assemble this composite signal are clocked from the phase continuous Fsc and 2 Fsc signals from the timing section.

When PAL is being generated, the action in quadrants 1 and 3 are swaped on alternate lines.

GRAPHIC GENERATORS

First a word about pixel size. The 5.7 MHz (4Fsc/2.5) pixel rate was originally choosen to give a square pixel. A pixel balances the resolution horizontaly and This balance allows moving objects to be vertically. rotated without distortion or designer intervention. It also allows simpler software for drawing lines and circles since the construction technique used can be mirrored on the 45 degree axis. Antialiasing algorithms can also be applied with ease when both axes are the same resolution. Other based on comparsion to the leading are advantages alternative, a 7.16 MHz (2 Fsc) pixel rate. With this higher pixel rate the pixels are no longer square, although this has not been a significant problem with our current system which has pixels with the same aspect ratio. With a goal of 40 characters per line, the faster pixel rate would use 8x8 pixel characters (320 pixels/line) and the slower rate would use 6x8 characters (240 pixels/line). The most obivous difference is the 33% larger data base necessary to support the smaller pixels. This data problem continues to the on chip character ROM requiring 40% more bits for a 7x8 matrix vs a 5x8 matrix. The 40 6x8 cards fit within the SMPTE "safe title area" making all cards usable vs the cards being left unused for critical two leftmost information or action. For moving object positioning, 240 pixels plus 16 pixels "under" the border is 256 X locations with the square pixels. This allows an 8 bit X register. Coupled with an 8 bit Y register, a 16 bit register conviently locates an object. The alternate is a 9 bit X location; requiring two register addresses and two writes to move the object. The finial advantage relates to "false" color generation. In the current Keyboard Component the high resolution alphanumerics, required careful pattern selection to avoid pixel combinations that directly or through harmonics created 3.58 MHz energy. The proposed 5.7 harmonic of an 8 pixel pattern (1 on 7 off, 2 on 6 off, 3 on art) foot checked, but I suspect that checked, but I suspect that none of those patterns have (his frequency amounts of 5th harmonic energy. The result is a great luma trender of shorts in foot patterns for the alphanumeric freedom of choice in font patterns for the alphanumeric The same freedom applies to the background and Chional characters. With the smaller pixels, even a grey and moving objects. white textured background can result in "false" color; it happens all the time on broadcast TV with striped ties and jackets, automobile grills and buildings with vertical decorations or windows.

BORDER

The border is divided into four quadrants. Each quadrant fills a corner and has its own color assignment. The division between the upper left and upper right corner color is a vertical line starting from any X location in the active picture area. A similar division is made along the other three sides of the picture. Each of the four dividing points are independently variable. One 16 bit register specifies the colors (4 bits/color) and two more 16 bit registers set the dividing points (8 bits/divider).

BACKGROUND

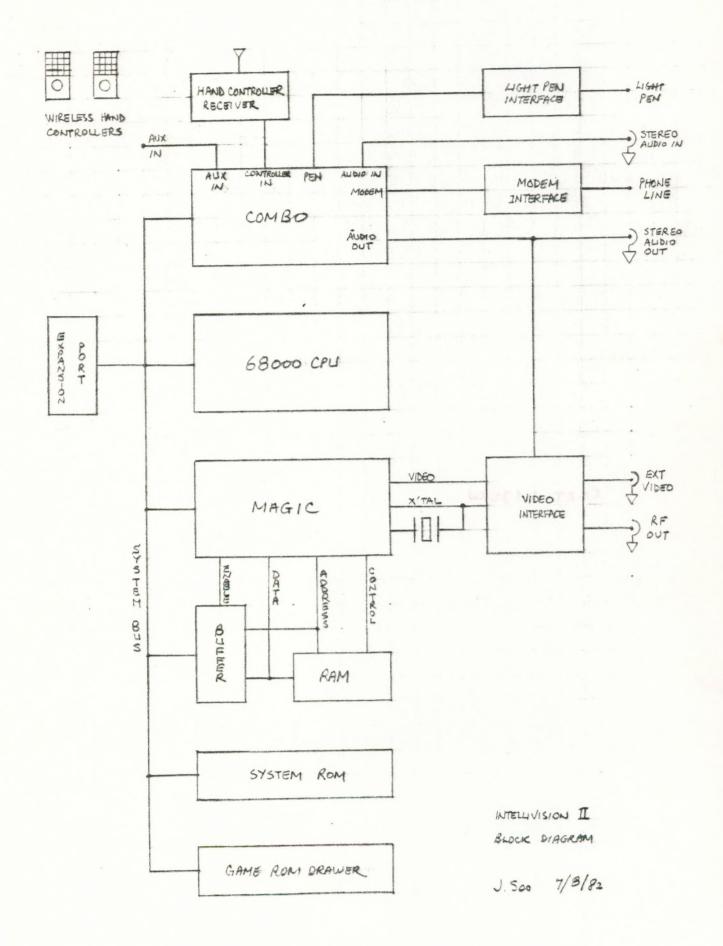

The background can be displayed in 3 modes: bit map, cards, and high resolution cards.

RBSØ - Moving Object Position

Register Bank Select & is a set of 16 registers, one for each of the 16 moving objects. Each register contains the position of the upper left-most pel of the associated moving object. The format of each register is as follows:

15		8 7	0
X	Position	Y Position	n

Bits 0-7: Y Position (\$ \le Y \le \frac{255}{208})

This 8-bit field contains the modern vertical position of the moving object in number of lines from the top of the screen. Since the "active" picture" starts on line 16 and there are 16 lines per moving object, Y position & places the moving object totally "under" the top border. Similarly, Y position 208 places the moving object totally under the bottom border

Bits 8-15: X Position (\$\leq \times = 255)

This 8-bit field contains the horizontal position of the moving object in number of pels from the left of the screen. Since the "active picture" starts on pel 16 and ends on pel 255, and since a moving object is 16 pels wide, x positions of and access it totally under the left walkers borders personately border and 255 leaves just the left-most pels exposed at the right border.

RBS1: Moving Object Parameters

Register Bank Select 1 is a set of 16 registers, one for each of the moving objects. Each register has the following format:

Hi R Si	× × ize Zoom	XMIR	HZZHS	HATER	Y size	7 200 m	YMIR
S	ize Zoom		S	ER	5 13e	200 m	IR
1				111		1	1
_	- V C - 1			111	V	Seale	7
	x Scale Factor				Y	Scale	

A "I"means the moving object's pels are "flipped", top for bottom value an axis running horizontally through its center.

Bits 1-5: Y Scale Factor (see discussion HALLA of Scale Factor)

This 5-bit field contains information for the vertical scale factor.

Bit 6: Interaction Enable

A "I" enables interaction detection and the reporting thereof in the interaction matrices RBS4 and RBS5.

MAGIC Registers RBS1: Moving Object Parameters (cont'd)

Bit 7: Invisible Color Enable

Lo-Res mode

A"1" enables pel color code Ø1 to indicate the "Invisible Color", i.e. transparent but able to interact.

A "0" allows the normal scheme whereby color code of selects Color 1 from the moving object's palette in RBS2.

Hi-Res mode

A"I" enables pel luminance code ØI to indicate the "Invisible Color" and to override the pel's color code.

A"Ø" allows the normal scheme whereby luminance code ØI selects 14 Adjustment and lets the pel color code select the color.

RBS1 (cont'd)

Bit 8: X Mirror

A "I" means the moving object's lines are "flipped", left for right about an oxis running vertically through its center

Bits 9-13: X Scale Factor (see discussion of Scale Factor)

This 5-bit field contains information for the horizontal scale factor.

Bit 15: High Resolution Enable

A "I" means the moving object's pel pattern is coded for the High Resolution display models and that it will be displayed as such.

RBS2: Moving Object Palettes

Register Bank Select 2 is a set of 16 registers, one for each of the 16 moving objects. Each register acts as a palette, or color menu, from which each pel of the associated moving object is assigned a color according to its 2-bit color code. In most situations, this 2-bit code acts as an index into the moving object's palette. (The palette in turn merely contains find indices into the Matter Palette.) The format of the Moving Object Palettes is as follows:

15 1:	2 //	87 4	3 0
moving obj	moving of	j. moving obj	moving obj.
color 3 index	index	index	index

Each 4-bit field contains an index into the 16-color Master Palette. Under some conditions, the contents of fields & and I may be ignored in the assignment of color to a pel. For destails, see the discussion of moving objects.

RBS3: Moving Object Pel Pattern Pointers

Register Bank Select 3 is a set of single - byte registers & (whose high order bytes do not exist). They contain pointers to the pel patterns of each moving object. These pointers are combined with the Moving Object Pel Pattern Base Address to form the addresses of each pel pattern. (See discription of register & of RBS7 for details of this scheme.)

RBS 4: Moving Object vs. Moving Object Interaction (Read-only)

Register Bank Select 4 is a set of 16 registers, one for leach of the 16 moving objects. Each bit position ascorresponds to a Jmoving object. The set of 16 registers, then, forms a 16×16 matrix which records interactions between moving objects. A "1" means the moving object of the register number and the moving object of the bit position number interacted un within the "active" picture" area (i.e. not under the borders). The diagonal entries will always be "". This means that moving objects do not self-interact (e.g. they do not stumble over their own feet). (The effect of a read operation is to reset all the bits

of the register to "P".)

RBS5: Moving Object vs. Background Color Interaction (Read-only)

Register Bank Select 5 is a set of 16 registers, one for each of the 16 moving objects. Each bit position corresponds to one of the background colors from the 16-color Master Palette. The set of 16 registers, then, forms a 16×16 matrix which records interactions between moving objects and colors forming the background. A "1" means that an interaction occurred in the "active" picture" area between a moving object of the register number and a background color of the bit position number. (The effect of a read operation is to reset all the bits of the register to "D".)

RBS6: Master Palette

Register Bank Select 6 is a set of 16 12-bit registers, Jeach containing chrominance information for one of the 16 colors (including tints and shades) that the programmer has chosen to be available for simultaneous display. The format of each register is as follows:

11	87	4	3 (2
V		RY	BY	
1		111	1	

The attached table shows examples of values of Y, RY and BY for various colors. Y can range from 0 to 15, and it is coded in normal binary notation. RY and BY may range from -8 to 7, and they are coded in excess-8 binary notation. To find the excess-8 form of a binary number, just add 8 to the number and disard they carry-out bit.

RB'S 6 (cont'd)	Proof.		0		M. 90/	W DV	Y-BY

*** BY actually 6 but forced to 5 so that Y+BY < 16

RBS7, Register & and some some Bits 0-7: Moving Object Pel Pattern Base Address Pel Pattern Base Address This & 8-bit field is combined with the A Pel Pattern Pointers for each moving object to form (from RBS3)" to form the word address of the first word of the each moving object's sel pattern. These addresses are formed as follows: Eastword addresses in Lo-Res mode: 8 bits (0-7) 1 4 Pel Patt. Pointer Base Address -for line count (16 lines) - word count (2-word fel pattern line descriptors) Note: This addressing requires Lo-Res pel patterns to begin on 32-word boundaries. in Hi-Res mode: 4 bits | Pel Patt. Pointer -for line count (16 lines) Base Address -word count (4-word 8 bits Pel pattern line descriptors) Note: This addressing requires Hi-Res pel patterns to begin on 64-word boundaries.

Bits 8-15: Background Pel Pattern Base Address

This 8-bit field is added to the each

background card's pel pattern pointer (from entries in the Background Table) to form the word address of each background card's pel pattern. These word addresses are formed as follows:

Note: This addressing requires background card pel patterns to begin on 8-word boundaries.

RBS7. Register 1: Background Address

This register contains to a 16-bit, address.

In Card mode, this is the address of the

Background Table. In Bit Map mode, this is

the address of the word whole-screen pel

11,520

pattern.

RBS7. Register 2 & Alpha Table Address

of a series of 480 words wide by 24 words high. This table which form a table 20 words wide by 24 words high. This table assertable words.

ASCII contains 760 a characters which will appear on the screen rows in left to right sequence, 40 characters per 24 rows per screen display.

The per screen display.

The larger by an amount 24 × 16n, where n is the number in the Alpha Excess

Sield.

RBS7, Register 3 (cont'd) ha Bit 7: Geraphan Alpha Display Enable MA SERREM A "1" enables display of the contents of the Alpha Table.

A "0" disables the Alpha display made. The Alpha display will be superimposed over any other display on the screen.

Bits 8-11 Accepted all and the Background Excess Card mode: In card mode, this 4-bit field contains the number of 16-(32-character) segments that MAGIC will assume have been added to each row of entries in the Background Table. After accessing 40 entries to display 40 cards on the screen, MAGIC will skip the designated number of 16-entry (32-words) before displaying the contents of the next This effectively widens the Background Table (without increasing the number of cards displayed at any one time), and it allows for limited horizontal scrolling without attering the table contents. In other words, each Excess count enables I horizontal scrolling for an extent of 16 cards. 1 Excess block normal Background Table wordo ptrn patr 0 2 80 55 40 39 row 1 959 1289 1343 921 1840 row 23 (up to 15 excess blocks

allowed)

RBS7, Register 3 m

Bits 0-3: Will Alpha Excess

This 4-bit field contains the number of 16-word (32-character) blocks that MAGIC will assume have been added to each row of the Alpha Table. After displaying the contents of 20 words to form a row of 40 characters on the screen, MAGIC will skip the designated number of 16-word blocks before displaying the contents of the next 20-word segment. This effectively widens the Alpha Table (without increasing the displayed information), and it allows for limited horizontal scrolling without moving the table contents.

RBS7, Register 3 (cont'd)

Bit 13: By External Video Enable

A "1" enables MAGIC to synchronize its internal clock with an external composite video signal.

Bit 14: Compande sand Interlace Disable

A "1" disables video display field interlacing.

Visually, the effect is to halve the interlacing line density

and to improve the appearance of the Alpha mode display.

Bit 15: Market Padeless Tolle Background Bit Mode Enable

A "1" enables the Bit Map mode (for background display).

A "O" enables the Card mode.

多

RBS7, Register 4

Bits 0-7: Con Divide Position Border Divide Position

This 8-bit field contains the number of the left-most pel that has the color of the right-side portion of the bottom border (i.e. the first pel of the second color,).

Bits 8-15: Bunker Warsalling Top Border Divide Position

This 8-bit field contains the number of the left-most pel that has the color of the right-side portion of the top border (i.e. the first pell of the supposition.

(See the diagram in the description of register 5.)

RBS7, Register 5

Bits 0-7: Benefitable strong Right Border Divide Position

This 8-bit field contains the number of the upper-most line that has the color of the lower portion of the right border (i.e. the first line of the second color,).

Bits 8-15: Banker Stranger Left Border Divide Position

This 8-bit field contains the number of the upper-most line that has the color of the lower portion of the left border (i.e. the first line of the second color,).

position

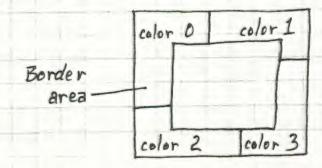

Illustration of Border Divides

RBS7, Register 6: Border Palette

This register consists of four 4-bit fields, each of which contains an index to one of the 16 colors of the Master Palette. Each field corresponds to a portion of the border and it selects the color for that portion. The register is formatted as follows:

Border	Border	Border	Border
Color 3	Color 2	Color 1	Color Ø

(See description of register 5 for a diagram of the arrangement of the colors.)

RBS7, Register 7

modes:

Bits 0-6: Mangres States - ASCII Code

This 7-bit field contains the ASCII code of the character whose pel pattern will be returned in register 8, word by word, in a & sequence determined phase by the Read Back the (see following field).

Bits 8-12: Mer Mer Berger From Read-Back Home Phase

This 5-bit field may take on ten values, each corresponding to one phase in the four possible Alpha read-back

Modes	mode	phase name	phase hex code
			1

RBS7, Register 8: Character Read-Back Pattern (Read-only)

Red Association

This register contains pel pattern information

This register contains pel pattern information for displaying the ASCII character whose code was placed in register the ASCII Code field of register 7. Eight segmential reads will provide all the information for the phase whose code resides in the Read-Back Phase field of register 7.

Generation

(See discussion of Character Read-Back)

Mostle Walter Daniel Harring Gold Williams

Bits O-11: - Background Card Priorities

This 12 bit field consists of three 4-bit

subfields, each containing a display priority level.

Card Priority Index

The 2-bit Associty Amber in each entry of the

Background Table will index one of these fields to

get a priority level available to colors on its

particular card. Griority 18 an exception as it

specifies "no priority level" for colors on its card.)

Bits O-Zillander Background X Burel

This 3-bit field contains the number of pel positions that the background will be shifted right on the screen. This value may vange from 0 to 5 (i.e. to I vless than a card width).

Bit 3: log byte styles & Border Extend

A "1" causes the vertical borders to extend inwards by 6 pels (i.e. a card width). This hides the junk "exposed" by horizontal background shifts.

Bits 4-6: MARGE BORRES FROTTAIN Background Y Shift

This 3-bit field contains the number of line positions that the background will be shifted downward on the screen. This value may range from 0 to 7 (i.e. to 1 line less than a card height).

Bit 7: My Border Extend

A "I" causes the horizontal borders, to extend inwards by 8 lines (i.e. a card height). This hides or Alpha the junk "exposed" by vertical background, shifts.

Bits 8-11: Markon Alpha X Seport

This 4-bit field contains the number of pel positions that the Alpha display will be shifted to the right on the screen. This value may range from 0 to 11 (i.e. to 1 pel less than it takes to display the two was ASCII characters contained in a word).

Bits 12-14: Gerage Rosen Alpha Y Shift

This 3-bit field contains the number of pline positions that the Alpha display will be shifted downward on the screen. This value may range from 0 to 7 (i.e. to 1 less than the winds of a row of Alpha characters).

Bit 15: Karynewson Alpha Border Extend

A "1" causes the left border in the to extend inward by 12 pels (i.e. 2 character widths).

This hides the junk "exposed" by thether horizontal

Alpha shifts.

RBS7, Register 11 (See discussion of screen splits.)

Bits \$-4: m Screen Split 2

This 5-bit field contains the line or pel position (divided by 8) of Screen Split 2.

Bit 5 = Alpha Screen Reverse

A "1" means that the roles of the primary and secondary screens are reversed for Alpha display.

Bit 684 Alpha Overlap Enable

on the primary screen and to begin at split 2 on the secondary screen. (Alpha split must be enabled.)

Bit 7 & Alpha Split Enable

on the primary screen and to begin at Split 2 on the secondary screen.

RBS7, Register 11 (cont'd)

Bits 8-12: m Screen Split 1

This 5-bit field contains the line or pel position (divided by 8) of Screen Split 1.

Bit 13: - Horizontal Split

A"1" means the lines splitting the Graphic and/or Alpha screen displays) between a primary and secondary screens run horizontally. A "0" means the split runs vertically.

Bit 14: a Graphic Overlap Enable

on the primary screen and to begin at Split 2 on the secondary screen. (Graphic split must be enabled.)

Bit 15 - Graphic Split Enable

A "1" causes the Graphic display to end on Split "1 on the primary screen and to begin on Split "1 on the secondary screen.

RBS7, Register 12 (Read-only)

Bits 0-8: m Current Line Count

This 9-bit field contains the number of the line which the is currently being refreshed on the screen. Reading this & register resets the interrupts, but the line count will not be affected.

Bit 98 m Line Count Interrupt Flag

A "I" means that the interrupt MAGIC generated for the 68000 was due to the current line Count matching the value in the Interrupt Line Count field. This bit will be reset to "B" when the register is read.

Bit 10: M Keal Time Clock Interrupt Flag

for the 68000 was due to the a "tick" of the Real Time Clock. This bit will be reset to "D" when the register is read.

RBS7, Register 13

Bits 0-8:4 Interrupt Line Count

This 9-bit field contains the number of the display line which MAGIC will generate an interrupt to the 68000 when it is nessested matched by the value of the Current Line Count.

Bit 98 the Line Interrupt Enable

A "I" means that MAGICAL generate an interrupt to

the 68000 when the Corrent Line Count matches the

Interrupt Line Count.

Bit 108 m Real Time Clock Interrupt Enable

A "I" means that MAGIC, senabled to
interrupt to the 68000 upon every "tick" of the

Real Time Clock.

Bit 11-12: ~ Chrominence Encoding Method

This 2-bit field contins specifies which stroke

Hollowing chrominence encoding method is being used. This is

chrominence encoding code

SECAM RGB PAL

50

RBS7, Register 13 (cont'd)

Bit 13: m Number of Lines

A "I" means that the screen display consists of 625 lines. A "O" means 525 lines comprise the display.

Bit 14: m Pel Density

A "I" means that the higher of two pel densities will be used and that the resultant active picture will be slightly smaller and the borders slightly wider. A"O" means that the lower pel density will be used.

Bit 15: * RAM Size

A "I" means that RAM is composed of 64k chips.

A "O" means that the chip size is 16k.

RBS7, Registers 14&15: Time-Out Registers

These two registers contain sixteen 2-bit fields, register 14 containing the low order bits and register 15 the high order bits. Each 2-bit field contains a code specifying the number of WAIT states normally involved in accessing each 32K portion of memory. Bits in the gero bit position pertain to the first (low) 32K, bits in the next position to the next 32k, etc. If the number of WAIT states exceeds the number required for normal access, MAGIC will generate the DTACK signal so as to avoid hanging up the 68000. The number of WAIT states allowed are coded as follows:

			U	1	1
der bit	1	0	1	0	1
T 11	ne and analysis to	0	7		
	der bit	on the summer that the natural contract is the state of t	nder bit: 0 nder bit: 0 T states: 8		

Since these values affect the basic functioning of the system, # the RESET initialization sequence should write them into registers 14 and 15 as soon as possible.

A background screen display consists of 192 lines, each line made up of 240 pels. The screen display may be logically divided into "cards", each card comprised of 8 lines, each line containing 6 pels. In this "Card mode", each pel is assigned a color and each card can have a selection of attributes, including degree of resolution and display priority. Alternately, in "Bit Map mode", the screen display may be logically monolithic, without degrees of resolution on priority, but with greater variety and complexity of coloration.

Each background picture (which may be larger than what can be displayed on the screen at ence) is described in memory by a "pel pattern". A pel pattern describes the color (and sometimes luminance) of each pel or trio of pels in the picture. These pel patterns may be on a card-by-card basis, as in the Card mode, or they may be for the entire background picture, as in the Bit Map mode.

CARD MODE Card Mode

In the Card mode, the displayed picture consists of 24 rows of 40 cards per row. The pel pattern for each card has a corresponding pointer which is part of the entry for each card in the Background Table. The pel patterns may encode pel information in the form required for either High or Low Resolution display, and colors may be assigned a display priority level which determines whether a given moving object would pass "behind" or "in front" of it.

Palette

BACKGROUND GENERATION

Wastell Woods Background Table
This table resides in memory and it consists of 960

2-word entries, each entry containing nations for

a particular card in the background diameter. 40 monds entries pertain to the 40 cards of the first row of the display (ordered left to right), and the next 40 entries pertain to the 40 cards of the second row, exceleration all 24 rows of the display. (See the description of Register 3 of RB57 for details of the Background Excess count.) Each 2-word entry is formatted as follows: Pel Pattern Pointer word o card card card word 1 color color

BACKGROUND GENERATION

where the fields are defined as follows:

Pel Pattern Pointer — This value is added to
the Background Pel Pattern Base Address (in pot
RBS7) to form the address of the first
word of pel pattern. These word addresses
are formed as follows:

Base Address 6 bits for line count

(8 lines)

note: This addressing requires card pel patterns to
begin on 8-word boundaries

Y Mirror - A "1" inverts the order of displaying

the rows of the pel pattern, i.e. they are "flipped" top for bottom.

X Mirror - A "1" reverses the order of displaying the pels of each row of the pel pattern, i.e. they are "flipped" left for right.

BACKGROUND GENERATION

Hi Res - A "I" means the pel patterns is coded for High Resolution mode display. A "B" means it is coded for Low Resolution mode.

(High and Low Resolution cards may be mixed in a display.)

2 Pri - A "I" means scard colors 3 and 2 take

on a priority level determined by the

Card Priority Index for this card. A "Ø"

means card colors 3, 2 and 1 take on

a priority level.

Card Pri - This is the Card Priority Index.

Values 0, I and 2 act as indices to select one

of the three priority levels available in register 9

of RBS7. The selected priority level becomes the

Card Priority Level and is then available to two or

three of the card colors as their priority levels.

Today walk 3 means up priority level is available for colors

BACKGROUND GENERATION

Lo-Res Pel Patterns -

The pel patterns in Low Resolution mode provide for selection of a color for each pel in a line. The colors available for selection are those specified in the selection are those specified in the seckground Table. Each word has the following format:

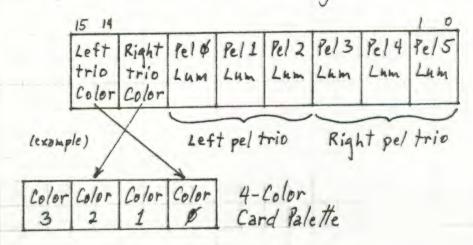

Pel is the left-most pel of a cardsline, and pel is the right-most. Each 2-bit field indexes one of the four colors in the 45 and Palette. Each subsequent word of the pel pattern describes the next lower line of the background card. They are arranged as follows:

C> word 0	line c
	•
word 7	line 7

a pel pattern for a Lo-Res card

Hi-Res Pel Patterns

Inminance information for each pel in a line and color information for horizontal groups of three pels at a time. The colors available are those specified in the Palette of the associated entry in the Background Table. The luminance specified may be one of four verels (or "adjustments"), the absolute value being dependent on the original luminance of specified in the color's unadjusted chrominance code. (These chrominance codes are the Y/BY/RY values given in the Master Palette, RBS 6. Each word of the pel pattern describes one line of the Hi-Res card, and it has the following format:

Pel & is the left-most pel of a card's line, and pel 5
is the right-most. Each 2-bit color field indexes one of the
four colors in the Card Palette and it does so for a trio of
pels. Each subsequent word of the pel pattern describes the
next lower line of the background card, just as in Lo-Res mode.
The following table maps the luminance code to the luminance
adjustment according to the Y value in the chrominance for the pel's
color:
Luminance code range of Y value

minance code range of 1 value $\frac{4-6}{7-9} \frac{7-9}{10-12} \frac{13-14}{13-14}$ 00

Color Priority

The relative priority levels of a moving object and a background pel determine whether the moving object passes "behind" or "in front" of that pel. When a moving object encounters a background pel, the item with higher priority level remains "in front". If both items thave the same priority level, the background pel stays "in front". stays "in front". The priority level of the moving object is simply equal to the moving object's ordinal number.
Moving Object & has low priority level, and Moving Object I has a higher priority level. The priority level of a background pel, on the other hand, results from a complex selection process which may even result in no priority level (which is less priority than zero). For a pel to have a priority level, it must:

1) be part of a Card mode display, 2) have Card Priority Index unequal to 3, and 3) have a color from the 4500 Palette that can have a priority level.

If a card's Card Priority Index in its Background Table entry is 3, its colors have no priority associated with them. If the Card Priority Index is 2, 1 or 0, it will index and select a priority level from register 9 of RBS7 and associate it with colors 3 and 2 of the card's representation Palette. If the 2-Pri bit is OFF in the card's Background Table entry, the selected priority level will also be lassociated with color 1 of the 169 A Palette. The following diagrams attempt to illustrate this scheme.

BIT MAP MODE

In the Bit Map mode, the background picture is not sub-divided into cards, each having a pel pattern. The address in register I of RBS7 does not point to an intermediate Background Table, but instead directly to one huge pel pattern. Each word of this pel pattern describes four pels. It takes 60 words to describe each of the 192 lines in a screen-size display, 11,520 words in all. The pel pattern words and the pel fields within them describe pels sequentially from left to right and then from top to bottom of the picture (although pels are arbitrarily numbered from right to left). The 4-bit pelmister fields contain an index into RBS6, the 16-color man la letter and therefore, in Bit Map mode, each pel may be assigned any one of sixteen colors, regardless of position. The format for a Bit Map pel pattern is as follows:

word 0	pel 2000 color	pel color	pel color	pel color	
word1	4	5	299	7	60 words describe
			6		1 line out of 192 lines
word 59	236	237	238	239	

CHARACTER GENERATION

The purpose of Character Generation is to allow generation of pel patterns for ASCII characters at runtime. The programmer writes the ASCII code of the character whose pel pattern he wants into the ASCII Code field of register 7 of RBS 7. MAGIC then passes pel pattern information back in register 8 (the Character Read-Back Pattern) of RBS 7.

Four Character Read-Back modes are available which provide pel pattern information for character displays of two sizes in both Card and Bit Map modes. These Character Read-Back modes are:

1) Card Normal

2) Card Double Width

3) Bit Map

4) Bit Map Double Width

Each mode consists of one or more phases. It takes eight consequtive reads of the Character Read-Back Pattern to acquire all the pel pattern information for a particular phase. The programmer may then change the Read-Back Phase codenfor and more information on the same character, or he may change the ASCII Code for pel pattern information of about a different character.

Display as a lighter

Versin of background.

No inwest video.

(used for displaying

VIDEOTEX)

1. Card Normal mode

This mode consists of one phase which provides information for a card-size (6 pels wide) pel pattern containing the image of one ASCII character.

Phase Code & (card Normal)

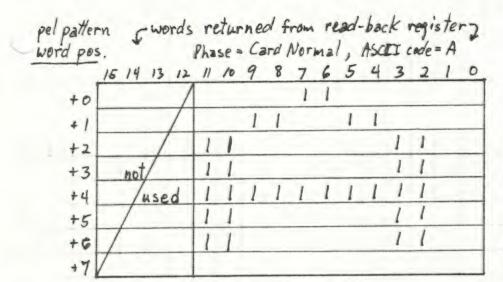

Each read of the Character Read-Back Pattern provides a word containing a line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the form was lined to the line of pel pattern in the line of pel pattern in

15 13	2					1 0
not used	pelo	pel 1 color	pel 2 color	pel 3 color	pel 4 color	pel 5 (ØØ)

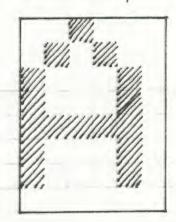

Each 2-bit field corresponding to a pel will be either Il or pp, where Il indicates a portion of the character image. The right pel, pel 5, will always represent the space between characters, and its pel field will therefore contain pp.

Luminouse shifts: 00+11.

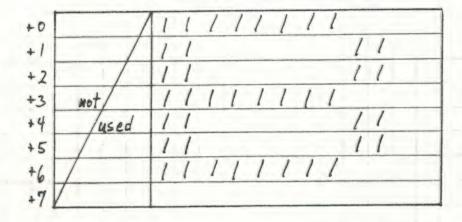

Card Normal Mode, example

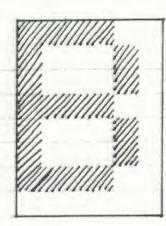

corresponding card display

Phase = Card Normal, ASCII code = B

2. Card Double Width mode

This mode consists of two phases. Together, they provide pel pattern information to display the character images two cards wide (12 pels). By doubling each line of the pel patterns, the programmer can restore the normal proportions of the scharacter.

Phase code 4 ("Left")

Eight consequtive reads in this phase provide the information for the left half of the character image. Each read provides a word in the format for Background cards:

15 1	2					1 0
not used	pel # color	pel 1 color	pel 2 color	pel 3 color	pel 4 color	pel 5 color

Each of the three pel fields pairs contain either IIII or popp, where IIII indicates two pels that are part of the character image.

Phase code Fis ("Right")

Eight consequtive reads in this phase provide the information for the right half of the character image. The returned words are formatted identically to those for the left half of the character except that pel fields 4 and 5 will always contain BOBO. This is because the night two pels represent the space between characters.

15 1	2					1 0
not used	pel & color	gel 1 color	pel 2 color	pel3 color	pel 4 (\$\$)	pel 5 (00)

3. Bit Map Normal mode

This mode consists of four phases. Together, they provide pel pattern information to display characters 6 pels wide (which includes / pel for a space). Each word of pel pattern contains a line two thirds of the width of a character. Thus, three words of pel pattern will span two characters, and the center word will contain the right is of the first character and the left is of the second character, The programmer must do the combining of character thirds by Oring the pel pattern words containing those two portions. Since this result Map display mode, one must remember that words describing horizontal lines of pels are consegutive in memory, whereas words describing vertical lines of pels are spaced 60 words apart.

Phase code 1 ("Left 33")

The eight words of pel pattern information returned by this phase is formatted as required by Bit Map background display mode:

			3 0
pelx.	pe/x+1		pe/x+3
color	color	color	color

The pels represent the left 3/3 of the requested character's image. Each 4-bit field contains IIII or \$1000, where 1141 represents a portion of the character.

Phase code 9 ("Right 13")

The eight words from this phase represent just the right 1/3 of the requested character's image. The remainder of each word represents a space or null (which are identical). They are formatted as follows.

			3
pelx+4 color	pe x+5 (0000)	null (OODO)	nu!! (0000)

char. rt. is space Pels representing a portion of the character have color code 1111.

Phase code 19,6 ("Left 1/3")

The eight words from this phase represent just the left is of the requested character's image. The remainder of each word represents a space or null. The format is as follows:

null (opp)	pelx+5 pelx+1	6 pel x+7 color	
Pels represe	space chi nting a portion of	ar. 18t. 1/3 the character have color c	ode 1111.

color	color		(\$\$\$\$)
FFO	r pp	1	space

Moving Object Pel Patterns and Display Priority

Images of moving objects are composed of pels within a 1/6×16 movable grid of pels. The pels defining the object are differentiated from neighboring pels within the grid by their compactly" (pels outside the object are made transparent). RBS 1 through RBS 3 in MAGIC and portions of memory (called "pel patterns") define the images of the 16 moving objects. The registers in RBS 3 contain pointers to each of the pel patterns. MAGIC adds these pointers to the Moving Coject Base Address in register Ø of RBS 7to get the beginning address of each pel pattern (see description of that register for details). Given appropriately coded pel patterns, each moving object may be displayed in one of two modes: Low Resolution or High Resolution. When the value of the Hi-Res bit in the moving object's parameter register in RBS 1 is "Ø", the moving object's display mode is Low Resolution ("Lo-Res"). When it is "1", the display is High Resolution ("Hi-Res").

Lo-Res mode

Pel patterns in the Lo-Res mode allow for two or three choices of color (and only color) for each of the pels forming the moving object image. Thirty-two words comprise each Lo-Res pel pattern, two words per line of the 16x16-pel grid, starting at the top line. Because of the way MAGIC steps through it, the pel pattern must begin on a 32-word boundary. The format for each two words of pel pattern is as follows:

	15 14	MARK & STREET, MARKET P. C. L. MARKET	Z	10	
worl of					MSB of Color
word p					LSB of Golor
WVI	Icolor code fo	r		righ	code for t pel

1

Corresponding bits from both registers form a 2-bit color code for each pel. The following table maps the color code:

color code	color assigned
00	"Absent" color
01	Color 1 if INVIS = 0
	"Invisible" color if INVIS=1
10	Color 2
11	Color 3

Colors 1, 2 and 3 are those having indices in like-numbered fields of the moving object's palette in RBS 2 (i.e. Color 1 refers to the Moster Palette color whose index is in field 1 of the moving object's Palette in RBS 2).

The "Invisible" color is available as a result of the INVIS bit being on in the moving object's Parameters register in RBS 1. It is transparent lie. colors behind it show through), but it can interact. The "Absent color is also transparent, but it cannot interact (it "isn't there"). The Absent color is used for "carving away" portions of the 16x16 grid which do not form part of the moving object's image. The Invisible color is useful for extending small speedy objects, such as bullets, to assure interaction detection although the "contact" may have occurred between frame displays."

HI-Res mode

Pel patterns in the Hi-Res mode allow for four choices of color for each pair of pels and for several levels of luminance for each pel. The way the luminance information is expressed depends on whether the pel is an Edge pel or a Body pel. A Body pel has its BODY bit equal "I", and its luminance code modifies the color's normal luminance Y that is specified by its Y/BY/RY chrominance code. An Edge pel has its BODY bit equal "B", and its luminance code results in various ratios of blending of the luminance of the pel with the luminance of the pel "behind" it.

Sixty-four words comprise each Hi-Res pel pattern, four words per line of the 16x16-pel arid, starting at the top line. Due to the way MAGIC addresses each word, the pel patterns must start on a 64-word boundary. The format of set of four words of pel pattern is as follows:

	15 14	2 1 6	
word &			MSB of Luminance
1	WIIII		LSB of Luminance
2			BODY bit
3			Color
	Icolor code for		
	left pel pair		
1	- luminance code for		
	left-most pel		

The following table maps the color code for each of

the 8 pel pairs:

color code color assigned from Palette

color Color D

color 1

color 2

Color 2

Color 3

The following tables map the luminance code for each pel:

Body pel (BODY=1): range of Y value of pels color luminance code 4-6 7-9 10-12 13-14 00 (value added to pel's Y value +2 -2 01 +2 -2 +4 10 +2 +4 +6

Edge pel (BODY = \$):

luminance code	luminance assigned
00	"Absent" luminance YAY + 34Y' if INTS = \$
01.	144 + 344 if INIS = \$
	"Invisible" laminance if INVIS = 1
10	1/2Y+ 1/2Y
11	3/4 Y + 1/4 Y

where Y is the Y value in the chrominance rade of the "rear" pel.

The Absent and Invisible luminances are analogous to the Absent and Invisible colors in Lo-Res mode and they serve the same purposes for Hi-Res. The "rear" pel is a pel that is being covered by an Edge pel of a Hi-Res moving object. It may be part of the background or part of a moving object of a lower priority level.

Priorities

When ohe moving object encounters the image of another moving object on the screen, the moving object having the higher priority level passes "in front" of the other. Or when a moving object with priority level higher than that of a certain background color encounters that background color, the moving object passes "in front" of that background color. This means that the pels with higher priority level are displayed instead of pels of lower priority level whenever MALIC must make a choice. For moving objects, all pels of the object have a priority level equal to the number of the moving object, the higher number having the higher priority, and thus the terms "front" pel and "rear" pel refer to pels of higher and lower priority levels, respectively.

Scale Factor

The size of a moving object's image on the screen may be increased or diminished without altering or switching pel patterns. The facilities for doing this are the X and Y Scale Factor fields in the Moving Object farameters registers of RBS 1. MAGIC will repeat or delete certain lines or pels of the image to expand or shrink it by a scale factor which may range between 0.5626 and 8.0 in 32 unequal steps. The change of size may be in the X (horizontal) or Y (vertical) directions or both at once. By varying the scale factor in time, one may cause the moving object to "approach" or "recede" on the screen.

Each Scale Factor field is composed of two subfields called SIZE (2-bits) and ZOOM (3-bits):

	1 1
SIZE	ZOOM
1	4 1

By entering values from these two subfields into the following formula, one may calculate the scale factor:

SF = (z+9)2

here

SF is the Scale Factor

Z is the Zoom value

S is the SIZE value

(2-bits) SIZE		Scale Factor	No. of pels in one dimension

Word Addressing

The Motorola 68000 addresses bytes of memory. That is, it assumes conequtive bytes differ in address by one and that consequtive words differ in address by two. MAGIC, on the other hand, addresses words of memory. It assumes that consequtive words differ in address by one. The programmer can access MAGIC registers on a byte basis, treating them as words in memory, but when supplying addresses to MAGIC (or data that MAGIC will use to construct addresses), the programmer must be sure to allow for MAGIC's method of word addressing.

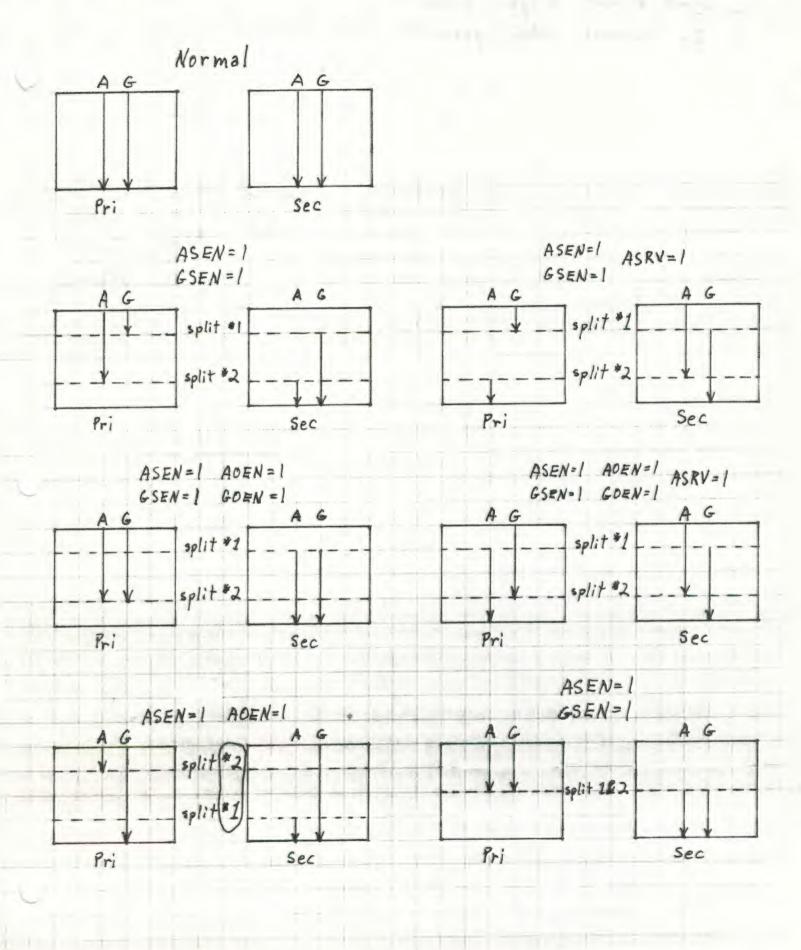

The fields affected by this consideration are:

- 1) Pel Pattern Pointers (both moving object and background)
- 2) Pel Pattern Base Addresses (" " "
- 3) Background Address
- 4) Alpha Table Address

When supplying data for these fields, the programmer need only first shift the data right one bit position within the field before writing it into the MAGIC register or entering it in a Background Table entry.

Screen Splits

Screen splits are for the purpose of dividing Alpha and/or Graphic displays between two screens so that each screen may contain information not ovailable on the other. The programmer controls this feature through the fields of register 11 in RBS 7. Normally, this entire register would be zeroed out, and the primary and secondary screens would have identical displays. The following examples illustrate the extents of the Alpha and Graphic displays on both screens when various combinations of fields in register 11 are set to non-zero. An "A" and an arrow represent the extent of Alpha display, and a "G" and an arrow represent the extent of Graphic display. The Horizontal Split flag is set (HOR=1) in all examples. Otherwise, all unlisted register 11 fields are assumed to contain zero.

 Display a background scene in high resolution cards mode that uses a large number of colors.
 This should give us some feel for the picture quality that we can expect to see in the new unit.

2. Have a moving object under user control (graphics tablet or thank controller) and move the object over the background that was created above.

This will show how well antialiasing works with moving objects and different colors.

- 3. Animate the moving object above. Test antialiasing again.
- 4. Draw several slanted parallel lines across the background so that they are not an integer number of card widths apart. See if there are any noticable bulges in the lines caused by the color limitations in high resolution cards mode.
- Add external video to the system. This is just to show if we have mechanized this properly.
- 6. Place 16 moving objects on one horizontal scan line. This is to make sure that Magic has the time to handle all of the moving objects.
- 7. Try to reuse each moving object several times. This should show our maximum apparent moving objects and should give us a feel for how many we really need. This will also test the programmable interrupt.
- 8. Reuse the moving objects while changing the color base for the moving objects. This increases the amount of work to be done by the processor. Once again, we can find out what our limits are.
 - 9. Perform a two-dimensional rotation on a moving object. This will show us if square pixels will do what we hope they can for us.
 - Rapidly change the background through a sequence of several pictures.
 This should give us a feel for the band width of the RAM.
 - 11. Try to draw some good looking three dimensional objects. See if shading gives us the effect that we want.
- 12. Zoom a moving object in the X and Y direction, the X direction only, and the Y direction only. See if it looks good enough.
 - 13. Use the split screen option to display half alpha and half graphics.
 - 14. Send different displays to separate t.v's.

- 15. In addition to the above tests, we need to be sure that software is developed to facilitate hardware debug. Every feature must be tested. A few of these features are listed below:
 - Normal Cards Mode
 - Total Color Spectrum
 - Interaction (If Done In Hardware)
 - Scroll (Both Full And Half Screens

Die Size Estimate

G.Daniels
S.Groves
T.Gunter

H.Scales
G.Schriber

G. Walker

The initial die size estimate for Mattel's custom design, which is referred to as MAGIC (Mattel Advanced Graphics Interface Circuit), has been completed. The information for the estimate has been accumulated over approximately three days of engineering meetings with Mattel and from incomplete schematics of the emulator which Mattel is currently designing. This estimate is 87,600 square mils, which is equivalent to a 296 x 296 mil die. It corresponds to a rough transistor count of 54,000 devices. The size is referenced to an "as drawn" dimension according to HMDS Tayout rules with a minimum channel length of 3.5 microns. This estimate is made with the understanding that not all information (in the form of schematics or detailed block diagrams) has been received from Mattel and, therefore, could increase if any additional functionality is deemed necessary. However, the estimate is submitted with the thought that it accounts for all functionality. "window" feature is not included in this estimate since it is not clear what exact implementation is desired.

Sufficient information does exist to make an accurate estimate despite the the fact that detailed design is still ongoing. This estimate reflects the particular architectural design which Mattel has explained. Little deviation has been made from their functional description except where thought was given to ease MOS layout or implementation peculiar to MOS technology. For any "black box" function (ie., where PRDM's are used to minimize

package count in the emulator) time was taken to derive a first pass logical MOS implementation to make a more accurate transistor count. This engineering estimate has been derived prior to actually doing any detailed MOS logic design. Estimates are normally refined on two occasions prior to actually beginning extensive layout design. Refinements occur when the logic diagram is complete after various timing problems are more thoroughly considered and then by layout designers in the process of doing detailed chip planning just prior to actually starting transistor layout.

The methodology used in the estimate was to accumulate active die area based on actual transistor count. This has been done in this case since no previous layout exists from a prior chip development. The transistor count for each particular function is then multiplied by a density factor to reflect how compact the function can be layed out in HMDS. This cumulative active area is then added to a routing overhead which is determined by multiplying a portion of the active area by a certain factor. Large areas such as a general purpose RAM or a large shift register structure have been assumed to not contribute to the routing overhead since they are a fairly closed structure and the functional circuitry around the large structure is well defined and contributes its own routing overhead. Attached you will find a listing of various functions and the compiled transistor count and active area that is believed associated with that function. More detail can be provided as needed. To this cumulative figure is then added the area requirements for the I/O buffers corresponding to the particular pin configuration and for internal power bussing which is typically associated with this size of chip.

The problem with trying to make a realistic estimate with this type of architecture, where there are roughly 130 addressable registers by the CPU which contain control and data information for distribution throughout the die, is that excessive routing can blow out the chip size. That is why a good layout plan for this chip is considered critical in order to minimize routing. The routing factor and density factors used in this estimate are ones typically found in good layouts.

I welcome and encourage the opportunity to meet with Mattel to go over the estimate in detail for the purpose of making sure there are not any errors and that all circuitry is accounted for in the estimate.

Sincerely, Mike Spak

HIGH RESOLUTION CARDS MODE

10/30/81

Note: References to this problem are on pages in my notebooks dated page before 10/30/81, 11/17/81, 12/2/81 and several pages 12/17/81.

The NTSC composite color video signal takes advantage of the eyes limited (compared to luminance) ability to resolve color. To this end the chroma components are limited to aproximately 0.5 MHz while the luminance uses about 3 MHz. These are bandwidths that are currently realized in the practice; the standards allow slightly greater bandwidths. If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like If I might make an analogy, the results are very much like I might make an analogy in the limitation is lacking.

What has all this to do with TV games? As we improve the resolution of the TV games, the pixel size gets smaller than the chrominance bandwidth can pass. Thus, if each of the pixels is a different color much of the information that is stored and sent to the TV is lost in the process of being stored and sent to the TV is lost in the process of being at a converted into and out of the NTSC signal. If we can make a converted into and out of the NTSC signal in formation in less data structure that stores the color information in greater detail, we detail and the luminance information in greater detail, we detail and the data storage requirements and better match can optimize the data storage requirements and better match the information carrying ability of the NTSC (and PAL and SECAM) signals. All of this adds up to better pictures at

The basic plan is to group the pixels and give a color to each group. To put the detail in, the luminance level of each pixel will be specified to add shadows and highlights, perform antialiasing and define the edges for the eye. Since we are going to arbitrarily group the pixels, there are going to be cases where more than one color is present in a group. In this case the color assigned to the group will be that of the majority (except in a few special cases, primarily involving narrow lines against a different color background). How does the eye know that the few pixels are of a different color? Very likely, there will be other pixels of the same color next to, above or below them. The plan is to make their luminance levels match that of their friends and the eye will do the rest. The number of pixels grouped together should bear some relationship to the color resolution; certainly, it would be wasteful to use more than twice the resolution and using less than the color resolution will degrade the picture. The exact ratio will likely be determined some other system requirements.

A specific implementation of this method is the High Resolution Cards Mode proposed for MAGIC (Mattel Advanced Graphic Interface Circuit). For MAGIC the normal resolution cards mode will consist of 24 rows each 40 cards long. Each card will contain 8 lines of 6 pixels each. Each card will be capable of displaying 1 of 4 colors at any pixel location; these colors will be 4 out of 16 stored in the color palette RAM map. Since we will be using a 16 bit wide data bus to the RAM, it will be easiest to get 16 bits for each line of each card. Each line of a card is 6 pixels wide; the 16 bits are taken two at a time to select 1 of the 4 colors from the card color map. For 6 pixels this only requires 12 bits leaving 4 bits unused.

In High Resolution Cards Mode, we find a use for those extra 4 bits. By grouping the pixels into two groups of three, the color for both groups can be set using the extra 4 bits. grouping results in a chrominance sample rate approximately four times the NTSC chrominance bandwidth. The remaining 12 bits in the 16 bit word are used, at two bits per pixel, to modify the luminance level. In MAGIC the output DAC has four bits of input and hence 16 levels Eleven of these are used for gray scale. The two assigned for luminance adjustment define four output. adjustment levels. One of these is no change from the luminance specified in the color palette RAM map. The remaining codes functions depend on the luminance level specified in the color palette (4 through 14 are the codes for the 11 gray scale levels):

Level Adjustment Available (gray scale levels)

4 to 6 6 +2, +4, +6

7 to 9 0 -2, +2, +4

10 to 12 0 -4, -2, +2

13 and 140 -6, -4, -2

In this specific case the technique uses the same amount of data more efficiently, allowing better pictures; in other cases the amount of data for the same picture quality could be reduced. While in this case a relatively complex method is used to adjust the luminance level, other methods including, but not limited to, fixed adjustments up and down and absolute luminance specification could be used.

A software/hardware simulation of the High Resolution Cards Mode as described above has been completed with excellent results.
